Abstract— An innovative approach to the generation of reverberation time series and echo detection algorithms is presented. The time series approach utilizes recent developments in linear spectral prediction research in which the spectra of stochastic processes are modeled as rational functions and algorithms are used to efficiently compute optimal estimates of coefficients which specify the spectra. The approach taken in this paper is to detect echo signal in two steps. In the first part the reverberation time series is generated using autoregressive formulation and in the second part echo is detected using order partition prewhiten algorithm.

Keywords- Active sonar, Reverberation, Autoregressive model, Reverberation spectrum, pre-whiten

I. INTRODUCTION

SONAR is an acronym for sound navigation and ranging. Sonar is a system that uses transmitted and reflected underwater sound waves to detect and locate submerged objects or measure the distance of underwater target. Sonar Reverberation (and radar clutter) has been modeled in a variety of ways and for a diversity of applications. Expected reverberation power (intensity) level models are perhaps the most common. In these, the expected reverberation power level at the input, output, or some intermediate point in the sonar (radar) system is estimated as a function of the environmental and system parameters. The models are useful in evaluating system performance for signal processing approaches which depend primarily upon power level, such as single beam energy detectors and matched filters. The time series simulation models can be developed to generate complex (in phase and quadrature) reverberation voltage levels in time series form, as they would occur at some point in the sonar system. The time series data can be run through emulations of alternative signal processing algorithms to evaluate relative performance of the various processes.

Reverberation is caused by seabed, sea surface and the inhomogeneity of the granule in the seawater. As a noise, reverberation can influence the detection performance of target echo and cause some serious problems to active sonar. Due to the fact that reverberation and target echo are correlative and their spectrums are close, how to restrain reverberation is a problem necessary to be solved for active sonar. In order to restrain the reverberation signal we are using pre whiten method here. The principle of this method is that an AR model is established from reverberation and then a whiten filter is designed using the power spectrum of this model.

II. TIME SERIES MODELING

Recent developments in linear spectral prediction (UP) techniques allow stochastic processes to be modeled in a straightforward manner. Common time series models of sampled stochastic processes, which are basic to many LSP techniques, include autoregressive (AR), moving average (MA), and autoregressive moving average (ARMA) processes. These processes can be realized as the outputs of linear digital filters driven by white noise processes, where the filter transfer functions have all-pole, all-zero, and pole-zero realizations for AR, MA, and ARMA processes, respectively. The digital filters can be implemented as recursive infinite impulse response (IIR) filters for AR and ARMA processes, and as a transversal finite impulse response (FIR) filter for an MA process. If the stochastic process to be modeled is non

Sowmya and Chandra,
Study of Reverberation Time Series and Echo Detection Algorithm in Reverberation Limited Scenarios
stationary: but quasi-stationary, the digital filter realization is time varying, with time-varying poles and/or zeros.

A. Autoregressive Process

In an auto regressive model of order p, the value $\bar{x}_n$ of the complex stochastic process at time n given as a linear combination of past values and a random input $\xi_n$, such that

$$
\bar{x}_n = -\sum_{k=1}^{p} b_k \bar{x}_{n-k} + \alpha \xi_n
$$

(1)

Where $\xi_n$ is a complex white noise process with zero mean and unity standard deviation. The system transfer function $H(Z)$, between input and output is represented in terms of model parameters as an all pole function.

$$
H(z) = \frac{\sigma}{1 + \sum_{k=j}^{p} b_k z^{-k}}
$$

(2)

The poles of $H(Z)$ are the zeros of the polynomial in the denominator and the number of poles p is referred to as the model order. The discrete power density spectrum is

$$
p_m = \frac{\sigma^2 \Delta f}{\left| 1 + \sum_{k=1}^{p} b_k e^{-j2\pi nk/M} \right|^2}
$$

(3)

Where $\Delta f$ is the sampling interval and $p_m$ is the power at radial frequency. The problem of modeling an arbitrary stochastic process $\{x_n, n = -\infty, -1, 0, 1, \ldots\}$ as an AR process reduces to the selection of the model parameters. The manner in which they are selected will depend on a priori information about $\{x_n\}$. A standard formulation is to select the model parameters such that the linear estimate of the process $\{x_n\}$ at the present time n, given the past p values of the process $\{X_n - k, k = 1: 2, \ldots, p\}$, is best in a least squares sense. That is, defining the linear estimate of order p as

$$
x_n^* = -\sum_{k=1}^{p} b_k x_{n-k}
$$

(4)

the parameters are selected such that the estimation error is minimized in a mean square sense

$$
\min_{\{a_j\}} E\{\varepsilon_n^2\} = \min_{\{a_j\}} E\{(x_n + \sum_{k=1}^{p} b_k x_{n-k})^2\}
$$

(5)

This is the digital Wiener optimal one-step prediction filtering problem, and it leads to the specification of the $\{b_k, \sigma\}$ as the solution of the normal equations

$$
\rho_m = -\sum_{k=1}^{p} b_k \rho_{1-k,n} \quad i=1,2,\ldots,p
$$

(6a)

$$
\rho_{on} = -\sum_{k=1}^{p} b_k \rho_{kn} + \sigma^2
$$

(6b)

where $\rho_{i-k,n}$ is the time-varying autocorrelation function of the non-stationary process.

$$
\rho_{i-k,n} = \Delta E\{x_{n-k}x_{n-i}^*\}
$$

(7)

If the spectrum (which in general is time-varying) of the process is known, then the auto-correlation function can be found by inverse Fourier transformation and the parameters $\{b_k, \sigma\}$ evaluated. If the spectrum is not known, but one has the past p values of the process, as in the above Wiener filtering formulation, then the auto covariance function can be used as a local estimate of the autocorrelation function.

$$
\phi_{i-k,n} = \Delta \left[ \sum_{j=n-p-i}^{n-i} x_{j-k} x_{j-i}^* \right] \quad i<k \quad i>k
$$

(8)

The auto covariance function can then replace the autocorrelation function in the normal equations. With this replacement, are known as the Yule-Walker equations and will be referred to in this way in this paper, regardless of whether the auto covariance or autocorrelation functions are used in them. A variety of ways to solve the Yule-Walker equations are available. We will use the Levinson-Durbin approach.

Having solved for estimates of the model parameters in this way, one can evaluate the spectral estimate or the linear estimation filter transfer function $&z$ by using the parameter estimates in expressions (3) and (2), respectively.

The filter will produce a statistical realization of the process $\{x\}$ when driven by white noise. The spectral estimate is sometimes referred to as the maximum entropy spectral estimate.
The Levinson-Durbin algorithm is utilized to solve the Yule-Walker equations to obtain the optimal set of non stationary poles, or more precisely, the optimal set of non stationary filter coefficients for each beam.

The generation of coherent reverberation which is correlated between beams and overlapping spectra is illustrated in Fig.3, where $H_a$, $H_b$, ..., $H_n$, represent transfer functions of the linear filters associated with beams, a, b, ..., n, respectively.

### III. REVERBERATION SPECTRUM MODELING

The generation of a time series based on the existence of a spectrum was discussed. Here, an approach to generating the expected spectrum for sonar reverberation as a function of pertinent sonar system parameters and environmental conditions is presented. The approach is a numerical evaluation scheme based on a spatial grid approach of Ackerman for a general formulation of reverberation developed by Faure, Olshevskii and Middleton. This leads to the computation of surface, volume, and/or bottom reverberation spectra and Dower levels as a function of:

- transmit signal waveform and power level,
- spreading and absorption propagation losses,
- backscattering strength,
- transmit and receive beam patterns,
- sonar platform-ocean geometry, and
- sonar and scatter motion.

The formulation represents reverberation spectra at the input of a receiver after beam forming, but prior to signal processing operations. The reverberation is non stationary, in that the spectra vary with time (and range), both in their spectral shape and their power levels. The reverberation is quasi stationary, in that the rate of change with time is assumed to be small relative to the transmit pulse duration (or the reverberation correlation time). Although the formulation can be extended to relax some of the following intrinsic assumptions include:

- primary scattering only,
- iso-sound-speed ocean,
- direct propagation path,
- narrow-band transmit signals,
- back scattering is from a large number of randomly distributed weak discrete scatters,
- radial velocity distribution of scatters is spatially uniform.

#### A. Faure, Olshevskii and Middleton Formulation:

The power density spectrum $P_f(f,r)$ of the reverberation envelope at the receiver input from scatters at range $r$ and frequency $f$, letting * designate the convolution operations given by

$$P_f(f,r) = \sigma^2(r)Y_f(f,r)*|S_{T_f}(f)|^2 \ast D_f(f)$$  \(9\)

Where

- $\sigma^2(r)$ = total reverberation power from scatters at range $r$,
- $Y_f(f,r)$ = Sonar motion envelope (power density) spectrum resulting from sonar motion and stationary (non moving) scatter at range $r$,
- $S_{T_f}(f)$ = Transmit signal envelope (energy density) Spectrum,
- $D_f(f)$ = reverberation power density ($P_f(f,r)$).

$$\int_{-\infty}^{\infty} Y_f(f,r)df = 1$$  \(10\)
The reverberation power levels are given by

\[ S_s = 10 \log s_s \]

\[ = 3.3 \beta \log(\theta_b/30) - 42.4 \log \beta + 2.6 \]  

(18)

The bottom backscattering strength can be represented as

\[ S_B = 10 \log s_B \]

\[ = 10 \log(\sin^2 \theta_b) - 27 \]  

(19)

The sonar motion envelope spectrum for volume, surface, and bottom reverberation, for a sonar moving at constant speed \( v_0 \) and constant direction are given by

\[ Y_{vj}(f, r) = \left\{ \begin{array}{l} \frac{\partial \Pi}{\theta B 0} \left\{ \int \frac{b_{TR}(\theta, \psi) \exp \left( 0 \frac{j 4 \Pi \nu T}{\lambda} \right) d \psi d \theta \right\} \\ \int b_{TR}(\theta, \psi) \cos \theta_s d \psi \\ \frac{\Pi}{0} \int b_{TR}(\theta, \psi) \cos \theta_s d \psi \end{array} \right\} \]

(20)

\[ Y_{Bj}(f, r) = \text{same as } Y_{vj}(f, r) \text{ except } \theta_S \text{ replace } \theta_B. \]  

(22)

Where

- \( b_r(\theta, \psi) \) = transmit power beam pattern
- \( b_n(\theta, \psi) \) = receive power beam pattern

The surface backscattering strength can be represented as a function of surface grazing angle \( w \) and speed, and frequency \( f \) through models such as the Chapman-Harris model

\[ S_B = 10 \log s_B \]

\[ = 158(\psi^{0.33})^{-0.58} \]  

Fig. 4. Spatial Division Of Reverberation Field.

The power density spectrum \( P(f, r) \) of the reverberation envelope given by (9) is evaluated numerically dividing space into a set of cells, as illustrated in Fig. 6. The ocean is divided into spherical shells which represent the portion of the ocean that is ensonified by the signal wavefront at particular instants of time after transmission (and corresponding ranges). The

\[ b_{TR}(\theta, \psi) = b_r(\theta, \psi) + b_n(\theta, \psi) \]

(16)
spherical shells are subdivided into a grid with three types of cells corresponding to those which contribute to surface, volume, and bottom reverberation. The location of each cell is defined by the range and the azimuth and elevation angles to the center of the cell relative to the platform velocity vector.

**IV. DETECTION OF ECHO SIGNAL IN REVERBERATION**

**BACKGROUND**

Reverberation is caused by seabed, sea surface and the in homogeneity of the granule in the seawater. As a noise, reverberation can influence the detection performance of target echo and cause some serious problems to active sonar. Due to the fact that reverberation and target echo are correlative and their spectrums are close, how to restrain reverberation is a problem necessary to be solved for active sonar. In order to restrain the reverberation signal we are using pre whiten method here.

**A. Pre-whiten method**

The principle of this method is that an AR model is established from reverberation and then a whiten filter is designed using the power spectrum of this model. Reverberation data is considered as Gaussian color noise. And the spectrum transformations between adjacent data segments are not obvious. The rationality of this hypothesis has been verified. The performance of this method is nicer even echo-reverberation ratio is comparative low. On the premise of this hypothesis, a method using all pole pre-whiten filters is proposed based on AR model at first. Then, based on this model, order partition algorithm is brought forward in detail. The AR model of reverberation data is shown in equation (23):

\[ r(n) = \sum_{i=1}^{p} a_i r(n-i) + w(n) \]  

(23)

where w(n) is a Gaussian white noise with an average of 0, \{a1, a2, ..., ap\} are estimated using the adjacent segment data. And its power spectrum is shown in equation (2).

\[ S(w) = \frac{\sigma^2}{1 + \sum_{i=1}^{p} a_i e^{-j\omega i}} \]  

(24)

When the parameters ai of this AR model have been estimated, the system function of pre-whiten filter is as follows:

\[ H(z) = \frac{1}{1 + \sum_{i=1}^{p} a_i z^{-i}} \]  

(25)

Output data y(n) is obtained by data x(n) passing the above system function

\[ y(n) = x(n) * z^{-1}[H(z)] \]  

(26)

The parameters of this AR model can be estimated through autocorrelation method, Burg method, Lattice recursive algorithm and so on.

**B. Order Partition Pre-Whiten Algorithm**

Order partition pre-whiten algorithm means that the sampled reverberation data is processed according to time order. Firstly, reverberation data is partitioned into several segments. Supposing that the echo signal s(n) is included in the signal x(n) which is received by hydrophone during the observation time T. The pulse width of s(n) is Tp. Data x(n) is partitioned into several segments and the width of each segment is Tk.

Firstly, reverberation data is partitioned into several segments. Supposing that the echo signal s(n) is included in the signal x(n) which is received by hydrophone during the observation time T. The pulse width of s(n) is Tp. Data x(n) is partitioned into several segments and the width of each segment is T_D as manifested in Fig.1, where dT denotes offset between the adjacent kth and k+1th data segments. The following conditions should be satisfied when partitioning the data into several segments:

1. The width of each data segment should be equivalent to the usable signal s(n) in order to satisfy the requirement of local stationary.
(2) To ensure that the echo signal $s(n)$ is fully included in one segment, the width of $s(n)$ should be smaller than each data segment. The following in equation should be satisfied:

$$T_D > T_p$$  \hspace{1cm} (27)

(3) To ensure that the echo signal $s(n)$ is situated in the next adjacent data segment when $s(n)$ is not completely included in a certain segment, following in equation should be satisfied:

$$dT < T_D - T_p$$  \hspace{1cm} (28)

According to the actual situation, the width of each data segment is double of the usable signal and the data overlapping rate is $\frac{1}{2}$.

$$T_D = 2T_p$$  \hspace{1cm} (29)

$$dT = 1/2(T_D)$$  \hspace{1cm} (30)

Secondly, the AR model of the kth data segment is established. In the method, the system function of the prewhiten filter which is based on the kth data segment for the k+1th data segment is as follows:

$$H_k(z) = \frac{1}{1 + \sum_{i=1}^{p_k} a_{k,i} z^{-i}}$$  \hspace{1cm} (31)

Lastly, the output data $y_{k+1}(n)$ is obtained by passing data $x_{k+1}(n)$ through above system function:

$$y_{k+1}(n) = x_{k+1}(n) * z^{-1}[H_k(z)]$$  \hspace{1cm} (32)

The flow chart of order partition pre-whiten algorithm is shown in below figure.

```
Fig 7: Flow Chart Of Order Partition Pre-Whiten Algorithm
```

V. SIMULATIONS AND RESULTS

The reverberation power spectrum using faure,olshevskii, and middeleton formulation is obtained and according to the block diagram and the time series using autoregressive model is obtained.
This paper describes the approach to the numerical generation of reverberation time series and echo detection algorithm. On the premise of local stationarity of reverberation, a method using all pole partition pre whiten filters which is based on AR model is proposed. The simulation results indicate that this method is effective even in the background of low echo to reverberation ratio of input. Moreover, the order partition algorithm is the better approach for detecting the echo signal in reverberation background.
